

Recrd LMSR Prediction Market: Comprehensive Technical Implementation & Flow

1. Architectural Overview & System Lifecycle

In the Recrd prediction market ecosystem, the LMSR (Logarithmic Market Scoring Rule) Automated Market Maker is exclusively used to provide algorithmic liquidity for "long-tail" markets. By design, one binary prediction market is generated for every published video. Since it is impossible to guarantee that human market makers will provide liquidity for thousands of low-volume videos, LMSR mathematically guarantees liquidity at all times.

1.1 The Complete Lifecycle

- 1. Event Initialization (Oracle Setup):** When a video is uploaded, the Recrd backend creates a question identifier (e.g., "Will Video #123 reach 10,000 views in 7 days?"). The Admin's address is designated as the resolver/oracle for this market.
- 2. Condition Preparation (Global Ledger):** The Recrd Admin calls `prepareCondition(adminAddress, questionId, 2)` directly on the `ConditionalTokens` contract (the global ERC-1155 ledger). This registers the market and the Admin's resolution authorization.
- 3. Pool Deployment & Seeding (Liquidity):** The Recrd Admin/Factory deploys a brand new, isolated `LMSRMarketMaker` clone smart contract specifically for this video's market, seeded with initial `FKToken` funding provided by the Admin.
- 4. User Liquidity Provision (Optional):** Users can deposit `FKToken` directly into this specific `LMSRMarketMaker` contract to earn a share of trading fees. They receive LP tokens representing their pool share. The admin can dynamically allocate as much of this idle user-delegated liquidity as they wish to the active trading reserve to scale the `$b$` parameter (market depth) on demand.
- 5. User Trading:** Users predict the outcome by buying YES/NO outcome tokens from the `LMSRMarketMaker` clone. The pool calculates dynamic slippage, pulls `FKToken` from active reserves (or mints matching positions using user/admin collateral), and delivers outcome tokens to the user.
- 6. Admin Resolution & Fee Reward Sharing:** After 7 days, the video views are audited. The Recrd Admin concludes the outcome by calling `reportPayouts(questionId, payouts)` on the `ConditionalTokens` contract. The Admin also chooses the reward distribution ratio of collected trading fees for LPs.
- 7. Settlement & Payout:** Trading halts. Users holding winning tokens call `redeemPositions` on the `ConditionalTokens` contract to claim their `FKToken` collateral at a 1:1 payout ratio. Liquidity providers burn their LP tokens to withdraw their remaining principal + their share of fee rewards.

2. Core Smart Contracts & Deep Dive

Contract	Standard	Technical Responsibility
----------	----------	--------------------------

FKToken	ERC-20	The fundamental collateral of the platform. Used to fund pools, place bets, and pay out winnings.
ConditionalTokens	ERC-1155	The core accounting engine. It stores <code>payoutNumerators</code> upon resolution. It is the only contract authorized to mint or burn outcome tokens. It holds all locked <code>FKToken</code> collateral in escrow.
LMSRMarketMakerFactory	Custom	Clones the LMSR logic using EIP-1167 Minimal Proxies to save gas. Initializes the pool's funding and sets the trading fee (e.g., 2%).
LMSRMarketMaker	Custom	The AMM pool. It stores the <code>b</code> parameter (funding). It exposes the <code>trade()</code> function. It relies on the <code>Fixed192x64Math</code> library to accurately compute the logarithmic cost function on-chain.

3. Detailed Contract Interaction Diagram

4. Technical Example Scenario: Code-Level Execution

Market Context: "Will Video #999 reach 1M views by Friday?" **Collateral:** FKToken **Liquidity Parameter (b):** 1000 FKToken (Provides moderate slippage for low-volume video markets). **Fee:** 0% (Simplified for this mathematical example).

Phase 1: Pool Deployment and Initialization

The Recrd backend wants to subsidize the market liquidity.

1. The backend approves the `LMSRMarketMakerFactory` to spend 1000 FKToken.
2. It calls:

```
factory.createLMSRMarketMaker(  
    pmSystem,          // Address of ConditionalTokens  
    collateralToken,    // Address of FKToken  
    [conditionId],     // Array of condition IDs (just one for binary)  
    0,                 // 0% fee  
    whitelist,         // Address 0x0 (public market)  
    1000 * 10**18      // 1000 FKToken as 'b' parameter  
)
```

3. **Internal Logic:** The factory deploys the pool. The pool transfers 1000 FKToken from the backend to itself. It then calls `pmSystem.splitPosition(...)` which moves the 1000 FKToken into the `ConditionalTokens` contract escrow, and returns 1000 YES and 1000 NO tokens to the pool.
4. **State:** The pool now holds exactly `[1000 YES, 1000 NO]`. It has issued `[0 YES, 0 NO]` to the public.

Phase 2: Alice Trades (Buying 500 YES)

Alice calls `pool.trade([500, 0], 400 * 10**18)`.

1. **Cost Calculation (`calcNetCost`):** The contract uses the LMSR cost formula:
 - $q_old = [0, 0] \rightarrow C_old = 1000 * \ln(2) = 693.14 \text{ FKToken}$
 - $q_new = [500, 0] \rightarrow C_new = 1000 * \ln(\exp(500/1000) + \exp(0)) = 1000 * \ln(1.6487 + 1) = 974.07 \text{ FKToken}$
 - $netCost = C_new - C_old = 280.93 \text{ FKToken}$
2. **Slippage Check:** The contract verifies $280.93 \leq 400$ (Alice's `collateralLimit`). The trade passes.
3. **Transfer:** The pool transfers 280.93 FKToken from Alice to itself.
4. **Minting:** The pool calls `splitPosition` on `ConditionalTokens` with 280.93 FKToken. `ConditionalTokens` mints 280.93 YES and 280.93 NO and sends them to the pool.
 - *Pool Inventory:* Now holds 1280.93 YES and 1280.93 NO.
5. **Delivery:** The pool transfers 500 YES to Alice.
 - *Final Pool Inventory:* 780.93 YES and 1280.93 NO.
6. **Price Shift:** The marginal price of YES changes from 0.50 to: $P(YES) = \exp(500/1000) / (\exp(500/1000) + 1) = 1.6487 / 2.6487 = 0.622 \text{ FKToken/YES}$

Phase 3: Alice Sells 200 YES (Taking Profits Early)

A few days later, the video is performing well. The price of YES has risen to `0.80 FKToken`. Alice decides to lock in partial profits before the market officially closes. She does not need to find a buyer—the LMSR AMM mathematically acts as the buyer of last resort.

1. **Action:** Alice calls `pool.trade([-200, 0], 150 * 10**18)`.
 - The negative `-200` means she is *selling* 200 YES tokens back to the pool.
 - The `150` acts as a `collateralLimit` in reverse—it is the *minimum acceptable payout* she expects to receive in FKToken.
2. **Cost Calculation (`calcNetCost`):**
 - The pool calculates the cost difference. Because she is returning YES tokens, the pool's `q_yes` liability is decreasing.
 - When `q` decreases, the cost function `C(q)` outputs a *negative* number.
 - Assume the math computes a payout of `-155 FKToken`. A negative cost means the pool *owes Alice* 155 FKToken.
3. **Slippage Check:** The pool verifies that `155 >= 150` (Alice's minimum limit). The trade passes.
4. **Execution:**
 - Alice transfers `200 YES` back to the pool.
 - The pool transfers `155 FKToken` from its own collateral reserves back to Alice's wallet.
 - (If the pool's raw collateral runs low, it calls `pmSystem.mergePositions()` to burn its YES and NO pairs and retrieve more FKToken from the global escrow).
5. **Price Rebalancing:** By absorbing Alice's sold YES tokens, the pool's `q_yes` liability decreases. The LMSR formula interprets this as reduced demand, so the marginal price of YES automatically drops slightly (e.g., from 0.80 back to 0.78), preparing a fair price for the next trader. Alice has successfully taken early profits.

Phase 4: Admin Resolution

The video reaches 1.2M views on Friday.

1. The Recrd Admin audits the view count and confirms YES won.
2. The Admin calls:

```
pmSystem.reportPayouts(questionId, [1, 0]); // Index 0 is YES, Index 1 is NO
```

3. **State Change:** The `ConditionalTokens` contract permanently maps this `conditionId` to a payout numerator of `1` for YES and `0` for NO.

Phase 5: Settlement and Redemption

Alice sees she won and wants to claim her payout.

1. Alice calls directly into the global ledger:

```
pmSystem.redeemPositions(  
    FKToken,           // The collateral token to retrieve  
    parentCollectionId, // 0x0 for base conditions  
    conditionId,  
    [1, 2]             // The index sets for YES (1) and NO (2)  
)
```

2. **Burn & Release:** The `ConditionalTokens` contract looks at Alice's balance. It sees she has 500 YES. Since the payout for YES is `1`, it burns her 500 YES tokens and transfers exactly `500 FKToken` from its locked escrow back to Alice's wallet.
 3. **Financial Outcome:**
 - Alice spent `280.93 FKToken`.
 - Alice received `500 FKToken`.
 - Alice's net profit: `+219.07 FKToken`.
-

5. System Design Considerations for Recrd

1. **Funding Subsidies & The Parameter (Liquidity vs. Risk):** LMSR pools require initial capital to operate. When Recrd deploys a new pool, it must seed it by locking `FKToken` into the contract. This directly establishes the `** parameter**`.

What is the parameter? It dictates the "liquidity depth" of the market. It controls how many tokens a user can buy before the price shifts dramatically.

The Maximum Bounded Loss (): The genius of LMSR is that the pool's losses are mathematically capped. If everyone buys YES, the price curves to `0.999 FKToken`. At this price, buyers are paying `1 FKToken` to win `1 FKToken`, so the pool stops losing money. The absolute maximum the pool can ever lose is .

If $b=1000$, the maximum loss is $1000 * \ln(2) \approx 693 \text{ FKToken}$. Recrd must view this `693 FKToken` as a maximum possible "liquidity acquisition cost" per video. If users bet incorrectly (or if trades go both ways), the pool's loss decreases and it can even turn a profit via trading fees.

How to Tune the Dial for Recrd:

- **High (e.g., 10,000):** Use this for massive influencers. It provides **deep liquidity**—whales can buy thousands of tokens without the price spiking wildly, creating a fantastic user experience. The trade-off is a high maximum bounded loss (`FKToken`), so Recrd takes on more risk.
 - **Low (e.g., 100):** Use this for small creators. It severely limits Recrd's financial risk (max loss `FKToken`). However, it creates **shallow liquidity**. If a user tries to buy just 50 YES tokens, the price will instantly spike from `0.50` to `0.90` (high slippage), resulting in a poor user experience.
2. **ERC-1155 Interface:** The frontend MUST be configured to read ERC-1155 token balances to show users their portfolio, rather than standard ERC-20 balances. The `tokenId` is deterministically generated by hashing the `collateralToken`, `conditionId`, and outcome index set.
 3. **Batch Redemptions:** Users who bet on multiple videos do not need to redeem one by one. `ConditionalTokens` supports batch redemption, allowing users to burn multiple winning `tokenIds` and withdraw all accumulated `FKToken` in a single, gas-efficient transaction.
-

6. User-Delegated Liquidity Provision & Dynamic Fee Sharing

To scale liquidity across thousands of video markets without requiring the Admin to fully fund every market out-of-pocket, the system integrates a **User-Delegated Liquidity Provision** mechanism directly into the `LMSRMarketMaker.sol` contract.

This hybrid design allows each market maker clone to operate both as an AMM trade router and as an ERC-20 vault for stakers.

6.1 Liquidity Lifecycle Flow

1. **Initial Deployment:** The Admin deploys the market maker and seeds it with initial funding (e.g., 500 FKToken) to establish a baseline b parameter.
2. **User Staking (Instant Auto-Allocation):** External users call `depositLiquidity(amount)` to deposit FKToken collateral. In return, the contract mints LP tokens to the user 1:1, and **instantly auto-allocates** the deposited collateral to the active LMSR trading reserve, scaling b depth immediately.
3. **Trading Fee Accumulation:** Every trade executed via `trade()` collects a transaction fee. These fees accumulate in a dedicated `poolFeeCollected` state variable.
4. **Dynamic Reward Share:** The Admin calls `setFeeRewardDistribution(ratio)` to configure what percentage of collected fees is distributed to LPs as rewards (e.g., 80% to LPs, 20% to the protocol).
5. **Withdrawal:** Stakers can call `withdrawLiquidity(lpAmount)` to burn their LP tokens, automatically merging inventory on `ConditionalTokens` to release collateral, and withdraw their original principal plus their share of accumulated fee rewards.

6.2 Key Staking Functions & Risk Resolution Architecture

- `depositLiquidity(uint256 amount)` : Pulls collateral from staker, mints LP tokens 1:1, and instantly auto-allocates collateral to active b trading reserves.
- `withdrawLiquidity(uint256 lpAmount)` : Burns LP tokens, automatically merges inventory on `ConditionalTokens` to release raw collateral, and returns principal + earned fee rewards (**Resolves Concern 2**).
- `claimFeeReward()` : Allows stakers to harvest their accumulated fee rewards standalone without unstaking principal.
- `setFeeRewardDistribution(uint64 ratio)` : Admin function to configure the LP fee reward percentage. Executable **only once** and permanently locked (`isLPRatioSet = true`) to prevent admin governance rug-pulls (**Resolves Concern 4**).

6.3 Resolution Summary of Key System Concerns

1. **Concern 4 Resolution (Admin Fee Ratio Modifications):** The LP fee share (`lpRewardRatio`) is permanently locked once configured by the Admin. LPs can safely stake knowing their yield percentage cannot be altered. LPs can claim yield independently using `claimFeeReward()`.
2. **Concern 2 Resolution (LP Withdrawal Availability & Inventory Lockup):** User liquidity auto-allocates instantly upon deposit. When an LP withdraws (`withdrawLiquidity`), the contract automatically calls `ConditionalTokens.mergePositions()` to convert outcome inventory back into liquid FKToken collateral in a single atomic transaction. No manual admin intervention or withdrawal lockup occurs.
3. **Concern 1 Resolution (LMSR Bounded Loss & LP Protection):** Trading fees are charged on **both buy and sell trades**, continuously accumulating into `poolFeeCollected`. This double-sided fee accumulation provides a robust fee pool to cushion against LMSR directional bounded loss.
